HIGHLIGHTS

- Testing heteroskedasticity in predictive regression.
- Specification test for testing constancy of conditional variance when regressor is nonstationary.
- Heteroskedasticity exists for predictive regression of stock return with dividend-price ratio and earning price ratio as the predictors.

Abstract: In this paper, we propose the Cramér-von Mises type test statistic for testing heteroskedasticity in predictive regression when regressors are nonstationary. A Monte Carlo simulation study is conducted to illustrate the finite sample performance of the proposed test statistic and a real empirical example is examined.

Keywords: Cramér-von Mises test statistic; Heteroskedasticity; Nonstationarity; Predictive regressions; Specification test.

JEL classification: C12, C22.

1 Introduction

In the recent three decades, testing predictability of asset returns has not only attracted vast amounts of attention from financial practitioners due to its key component to evaluate mutual fund managers' performance, examine the validity of asset pricing models, and improve asset allocation efficiency, but also has been an important research topic in financial economics in academia. A large literature has been devoted to testing whether asset returns are predictable or not. The typical econometric method used in literature is an ordinary least squares (OLS) regression of returns versus the lag of the financial variables, and conventional t-statistics are used to check the significance of coefficients.

For easy exposition, a structural simple predictive regression model is given by

$$y_t = \beta_0 + \beta_1 x_{t-1} + u_t, \quad 1 \le t \le T,$$
 (1)

where x_{t-1} is a nonstationary time series. Here, $\operatorname{Var}(u_t | x_{t-1}) = \sigma_t^2$ might not be a constant. Then, u_t can be written as $u_t = \sigma_t \epsilon_t$, where $\{\epsilon_t\}$ is a sequence of iid random variable or a stationary time series with $E(\epsilon_t) = 0$ and $\operatorname{Var}(\epsilon_t) = 1$. Thus, (1) can be written as

$$y_t = \beta_0 + \beta_1 x_{t-1} + \sigma_t \epsilon_t, \tag{2}$$

where it is commonly assumed that σ_t is a constant and x_{t-1} satisfies the following autoregressive (AR) model

$$x_t = \rho \, x_{t-1} + v_t, \tag{3}$$

where $\rho = 1 + c/T$ for some unknown constant c, and v_t is a weakly stationary time series, say, an α -mixing process. Clearly, if c = 0, x_t is a unit root process, denoted by I(1) and it is nearly integrated process, denoted by NI(1), if c < 0. Under the assumption that σ_t is a constant and x_{t-1} satisfies (3), there is vast amounts of literature for testing the predictability as H_0 : $\beta_1 = 0$. The reader is referred to the recent survey paper by Liao, Cai and Chen (2018) for details on the various methods, from which, one can see that when x_t is nonstationary, the assumption that σ_t is constant is key to derive the asymptotic theory for testing H_0 : $\beta_1 = 0$. Recebbly, by extending the work by Park (2002), Choi, Jacewitzb and Park (2016) reexamined stock return predictability by assuming that $\sigma_t = \sigma_0(t/T)$ or $\sigma_t = \sigma_0(z_t/\sqrt{T})$ for some known function $\sigma_0(\cdot)$ to satisfy some conditions.

Therefore, by assuming that σ_t is possibly nonstationary and a function of x_{t-1} as $\sigma_t = \sigma(x_{t-1})$, it is of great importance to consider the following test problem; that is to test heteroskedasticity,

$$H_0: \sigma(\cdot) = \sigma_0, \tag{4}$$

where σ_0 is an unknown or known parameter. Of course, it would be interesting to consider other types of test.

The rest of the paper is organized as follows. The construction of the proposed test statistic is presented in Section 2 and Section 3 is devoted to presenting studies on the Monte Carlo simulations and real applications. Concluding remarks concludes Section 4.

2 Specification Test

Let $\delta = \operatorname{corr}(u_t, v_t)$. As argued by Campbell and Yogo (2006), δ might not be zero in many applications, so that the so-called *embedded endogeneity* causes the estimation bias for estimating

 β_0 and β_1 by running directly the model in (1). To overcome this difficulty, following Cai and Wang (2014), one can use a projection approach of u_t onto v_t as $u_t = \gamma v_t + \eta_t$ and run the following regression with estimated regressor

$$y_t = \beta_0 + \beta_1 x_{t-1} + \gamma \,\hat{v}_t + \eta_t, \quad 1 \le t \le T,$$
(5)

to estimate β_0 and β_1 , where $\hat{v}_t = x_t - \hat{\rho} x_{t-1}$ from (3), so that one can obtain the residual \hat{u}_t , from which $\hat{u}_t = u_t + O_p(T^{-1/2})$ based on Theorem 1 in Cai and Wang (2014) under some mild conditions. Therefore, by letting $r_t = u_t^2$ and $\hat{r}_t = \hat{u}_t^2$, we have

$$\hat{r}_t - r_t = 2\left[(\beta_0 - \hat{\beta}_0) + (\beta_1 - \hat{\beta}_1) x_{t-1} \right] \sigma(x_{t-1}) \epsilon_t + O_p(T^{-1}).$$
(6)

It is intuitively clear that the biases of the squared residuals are of order $O_p(T^{-1})$, and this is the effect of estimated β_0 and β_1 in (5) on the estimated variance function $\sigma^2(x)$. This result also paves the way for employing a fully data-driven bandwidth procedure in the estimation given in (7) below.

Since $\sigma^2(x_{t-1}) = E(r_t | x_{t-1})$, then, r_t can be written as a mean regression form as follows

$$r_t = \sigma^2(x_{t-1}) + \xi_t,$$

where $E(\xi_t | x_{t-1}) = 0$. Thus, under H_0 in (4), a consistent estimate of σ_0^2 is

$$\widetilde{\sigma}_0^2 = \frac{1}{T-1} \sum_{t=2}^T r_t$$

if r_t would be known. But, r_t is unknown in practice, it should be replaced by \hat{r}_t according to (6). Clearly, in view of (6),

$$\frac{1}{T-1}\sum_{t=2}^{T}\hat{r}_t - \tilde{\sigma}_0^2 = 2\sigma_0(\beta_0 - \hat{\beta}_0)\bar{\epsilon} + 2\sigma_0(\beta_1 - \hat{\beta}_1)\overline{x}\bar{\epsilon} + O_p(T^{-1}),$$

where $\bar{\epsilon} = \sum_{t=2}^{T} \epsilon_t / (T-1)$ and $\overline{x\epsilon} = \sum_{t=2}^{T} x_{t-1} \epsilon_t / (T-1)$, which can be easily shown that $\bar{\epsilon} = o_p(1)$ and $\overline{x\epsilon} = O_p(1)$. Therefore,

$$\widetilde{\sigma}_0^2 = \frac{1}{T-1} \sum_{t=2}^T \hat{r}_t + o_p(1) \approx \frac{1}{T-1} \sum_{t=2}^T \hat{r}_t \equiv \hat{\sigma}_0^2,$$

so that $\frac{1}{T-1} \sum_{t=2}^{T} \hat{r}_t$ is used to estimate σ_0^2 consistently.

Under the alternative, $\sigma^2(x_{t-1}) = E(r_t | x_{t-1})$ is a nonparametric function of x_{t-1} , so that based on nonparametric estimation procedure, one can estimate $\sigma^2(x)$ for a given x by the following kernel method (local constant approach) as in Han and Zhang (2012),

$$\tilde{\sigma}^2(x) = \sum_{t=2}^T r_t K_h(x_{t-1} - x) / D_T(x),$$
(7)

where $D_T(x) = \sum_{t=2}^T K_h(x_{t-1} - x), K_h(x) = K(x/h)/h$, K(x) is a kernel function, and h is the bandwidth satisfying $h \to 0$ and $Th \to \infty$. Note that different from the local linear estimation of $\sigma^2(x)$ for stationary case in Fan and Yao (1998), a local constant estimation is employed here since both have the exact same asymptotic behaviors for nonstationary regressors as argued in Cai (2011). Similar to Theorem 3 in Cai (2011) and Han and Zhang (2012), one can show easily that

$$\widetilde{\sigma}^2(x) = \sigma^2(x) + B_T(x) + O_p(T^{-1/5}) \tag{8}$$

where $B_T(x) = h^2 \mu_2(K) \ddot{\sigma}^2(x)/2$ with $\ddot{\sigma}^2(x)$ being the second derivative of $\sigma^2(x)$ and $\mu_2 = \int x^2 K(x) dx$. Based on the above discussions in (6) and (8), r_t can be replaced by \hat{r}_t , so that

$$\hat{\sigma}^2(x) = \sum_{t=2}^T \hat{r}_t K_h(x_{t-1} - x) / D_T(x).$$
(9)

Similarly, one can show that (8) holds true for $\hat{\sigma}^2(x)$, which implies that $\hat{\sigma}^2(x)$ is a consistent estimate of $\sigma^2(x)$.

To test H_0 , similar to the test in Cai, Wang and Wang (2015), we make use of the following weighted Cramér-von Mises test statistic (L_2 -type) test statistic

$$J_T = \int \left[\left(\hat{\sigma}^2(x) - \hat{\sigma}_0^2 \right) D_T(x) \right]^2 dx$$

which can be simplified, by removing by the global center, i.e., the sum where t = s in the above equation, as follows

$$S_T = \sum_{t,s=2} \sum_{t \neq s} \hat{\xi}_t \hat{\xi}_s W((x_{t-1} - x_{s-1})/h), \tag{10}$$

where $\hat{\xi}_t = \hat{r}_t - \hat{\sigma}_0^2$ and $W(u) = \int K(v)K(u-v)dv$ is the convolution kernel. Note that the reason of employing the weighted L_2 -type test statistic is to get ride of the random denominator, which has been commonly used in the literature.

Note that the test statistic in (10) is similar to the kernel smoothed test statistic, which has commonly been applied to test parametric specifications in the econometrics literature, see, for example, Zheng (1996), Fan and Li (1996), and Li (1999) for stationary time series mean regression and in Wang and Phillips (2012) for nonstationary regressor. Under some regularity assumptions, which are similar to Assumptions 1-5 in Wang and Phillips (2012), by following the proof in Wang and Phillips (2012), it is difficult to show that

$$S_T/\sqrt{2\hat{\Sigma}_T} \longrightarrow_D N(0,1),$$
 (11)

which is similar to (3.10) in Zheng (1996) for iid case, and (3.1) in Wang and Phillips (2012) for nonstationary situations, where

$$\hat{\Sigma}_T = \sum_{s,t=2} \sum_{s \neq t} \hat{\xi}_t^2 \, \hat{\xi}_s^2 W^2(x_t - x_s)/h),$$

which is the exact same as that for the iid case in Zheng (1996) and for time series context in Fan and Li (1996) and Li (1999) as well as for nonstationary time series in Wang and Phillips (2012). Also, one can show that the test statistic S_T is a consistent test.

3 Applications

To investigate the finite sample performance of the proposed test statistics, we conduct a Monte Carlo simulation study with constant and time-varying $\sigma^2(\cdot)$. For simplicity, in following computations, the Gaussian kernel is used so that the convolution kernel is an N(0, 2) density function.

3.1 Monte Carlo Simulations

The data generating process from predictive regression model is

$$y_t = \beta_0 + \beta_1 x_{t-1} + \sigma(x_{t-1}) \epsilon_t, \quad x_t = \rho x_{t-1} + v_t, \tag{12}$$

where $\beta_0 = 0.5$, $\beta_1 = 0.75$ and $\rho = 1 + c/T$ with c taking 0, -5, and -30. Clearly, the degree of persistence of x_t is controlled by nuisance parameter c and the three levels of persistence correspond to the cases when predictor x_t is a unit root process, a nearly unit root process and a stationary process, respectively. The innovations ϵ_t and v_t are jointly generated by standard bivariate normal distribution with correlation coefficient δ taking -0.95 and -0.25.

To study the finite sample performance of proposed testing method, we consider the following case:

$$\sigma^2(x_{t-1}) = \sigma_0^2 + \tau \, x_{t-1}^2,\tag{13}$$

with $\sigma_0^2 = 1$. When $\tau = 0$, it collapses to the null hypothesis so that the empirical test size can be computed. When $\tau \neq 0$, it reduces to a series of alternatives, which delivers the empirical power indexed by τ .

The Monte Carlo simulation is considered with T = 500 and 1000, $\delta = -0.95$ and -0.25, and three values for nuisance parameter c, and it is repeated 1000 times for each setting. In order to demonstrate the finite sample behavior of the proposed test statistic, we examine the sizes and the powers under three choices of bandwidth $(h_1, h_2, h_3) = (h, 0.5h, 1.5h)$ with $h = T^{-1/10}$ for c = 0 and -5, and $h = T^{-1/5}$ for c = -30. The test sizes are reported in Table 1, from which one can observe that the test sizes are close to the nominal size under all settings. Therefore, one can conclude that the test is not very sensitive to the choice of bandwidth as long as the bandwidth is in the reasonable range and performs very well. Now, we evaluate the power of the proposed test by two typical

		1				
		$\delta =$	-0.95	$\delta = -0.25$		
		T = 500	T=1000	T = 500	T=1000	
c=0	h_1	0.046	0.050	0.040	0.042	
	h_2	0.049	0.046	0.044	0.048	
	h_3	0.033	0.041	0.040	0.040	
c=-5	h_1	0.036	0.041	0.032	0.044	
	h_2	0.046	0.049	0.043	0.047	
	h_3	0.026	0.037	0.022	0.033	
c=-30	h_1	0.036	0.044	0.034	0.040	
	h_2	0.041	0.045	0.049	0.045	
	h_3	0.027	0.034	0.024	0.032	

Table 1: Size performance with nominal size 5%.

examples. Indeed, the power is computed by τ in (13) in the range [0,0.01] with an increment 0.001 when c = 0 and $\tau \in [0, 0.1]$ with an increment 0.01 when c = -30. The powers vary slightly with bandwidth but they are quite close in general, given such small increment in alternatives. Meanwhile, with smaller choice of τ in the series of alternatives when c = 0, the performance of proposed test statistic is better for nonstationary scenario than for stationary case in terms of test power. Figure 2 also demonstrates this property. In Figure 2, we fix the bandwidth $h = T^{-1/5}$ for all scenarios and compute powers by $\tau \in [0, 0.1]$ with an increment 0.01 when T = 500 and $\tau \in [0, 0.03]$ with an increment 0.003 when T = 1000. We also compute powers with $\delta = -0.25$, the results are almost the same and thus omitted for saving space.

3.2 An Empirical Example

As an illustration of our methodology, we test heteroskedasticity for predictive regression of stock return with dividend-price ratio and earning price ratio as the predictors. Two different series of stock returns are employed, the returns on NYSE/AMEX value-weighted index and S&P 500 index from the Center for Research in Security Prices (CRSP). We use monthly data from November 1926 to December 2019.

The dividend price (D-P) ratio is constructed as the ratio of average dividends during the last

Figure 1: Powers of the alternatives (13) with c = 0, $\delta = -0.95$ and T = 500 in the left figure and c = -30, $\delta = -0.95$ and T = 500 in the right figure.

Figure 2: Powers of alternatives (13) with $\delta = -0.95$ and T = 500 in the left figures and $\delta = -0.95$ and T = 1000 in the right figure.

year over the current price level, we take the natural log on it in actual predictive regression. For both indexes, the log D-P ratios have been identified as an I(1) process by ADF test and we first consider the following predictive regression

$$r_t = \alpha + \beta x_{t-1} + u_t, \tag{14}$$

where r_t is the excess return and x_t represents the associated log D-P ratio. Denoted by \hat{v}_t the OLS residuals from the AR(1) model, $x_t = \rho x_{t-1} + v_t$, and \hat{u}_t the OLS residuals from model (14). The sample correlation coefficients between \hat{u}_t and \hat{v}_t are reported in Table 2, these nonzero values imply the existence of embedded endogeneity (x_{t-1} and u_t may be correlated) problem which leads to biased estimates. Following Cai and Wang (2014), we employ the projection approach to deal with endogeneity problem and the regression model is

$$r_t = \beta_0 + \beta_1 x_{t-1} + \gamma \,\hat{v}_t + \sigma(x_{t-1}) \,\epsilon_t.$$
(15)

Our interest is to test heteroskedasticity; that is, test $H_0: \sigma^2(x_{t-1}) = \sigma_0^2$, where σ_0^2 is unknown. The test statistics and p-values of the test are reported in Table 2. With 5% significance level, both null hypotheses are rejected. This means that $\sigma(x_{t-1})$ depends on x_{t-1} .

In addition, we also consider the earning price (E-P) ratio as the predictor of stock return. The log E-P ratio is computed base on the cyclically adjusted price earnings ratio (CAPE), which is proposed by Shiller (Irrational Exuberance, 2016), to be specific, we take the natural log on the inverse of CAPE. We apply the same testing methodology and the results are also reported in Table 2, from which one can conclude that $\sigma(x_{t-1})$ depends on x_{t-1} in this application example as well.

		log D-P ratio		log E-P ratio						
	$\hat{\delta}$	Test Statistics	p-value	$\hat{\delta}$	Test Statistics	p-value				
S&P 500	-0.8409	5.3865	< 0.0001	-0.6589	2.6143	0.0089				
NYSE/AMEX	-0.9473	5.6063	< 0.0001	-0.6708	2.8815	0.0040
